Abstract: Harbor siltation is a problem that will exist as long as harbors exist and it is intrinsically linked to their primary function – providing shelter for anchorage and operative conditions for loading/unloading ships. In these semi-enclosed basins, flow characteristics are one of the main factors influencing siltation and water quality. One of the largest recreational ports of Europe, La Rochelle Marina (southwestern France), is not spared by siltation, which requires serious dredging operations during a major part of the year. In this context, a three dimensional model (TELEMAC 3D) has been used to investigate its hydrodynamics. Using a simplified approach, floating structures were implemented in the model. Comparison with observations has demonstrated the need to consider these structures in our study. They significantly reduce velocity in the inner parts of the marina and concentrate current on access channels. Numerical results also highlight the joint role of the macrotidal regime and wind stress in the movement of water masses and their residual circulation.

Author keywords: Hydrodynamics; Marina; Numerical modeling; Floating structures; Residual flux.

31 **Introduction**

32 Similar to every area protected from the combined action of waves and marine currents, ports suffer
33 siltation (Winterwerp, 2005). This siltation depends on environmental parameters, such as the local tidal range and
34 wave climate, meteorological conditions, and river input. Port siltation is also influenced by the planform geometry
35 and basin state of enclosure (Falconer, 1992; Nece, 1984). Furthermore, these areas are used extensively, and thus
36 require particular attention in terms of currentology, sediment deposition and water quality.

37 The increasing concern of planners and designers for hydro-environmental problems relating to semi-
38 enclosed environments fosters development of an operational modeling system. However, they are difficult to
39 model accurately due to their composite geometry (quays, channels, docks, etc.) affecting the circulation of water,
40 both occasionally and permanently. Indeed, docks and boats floating in the port could also play a substantial role,
41 by attenuating surface currents with friction and by decreasing wind action. Many modeling studies have been
42 carried out to investigate environmental and engineering problems at the harbor scale. For instance, Sanchez-
43 Arcilla et al. (2002) correlated the capacity to flush to hydrodynamics and Murphy et al. (2012) characterized dead
44 zone mixing processes in several marina configurations. In this paper, we focus on the effect of floating structures.
45 Indeed, although some studies have investigated the effect of currents and/or waves on floating docks (Tajali et
46 al., 2008; Ghadimi et al., 2014), few have investigated the influence of floating bodies on water circulation (Ligier,
47 2016).

48 The study site, La Rochelle Marina, located in southwestern France, is currently considered the largest
49 marina on the European Atlantic coast. Recently, in order to satisfy continued growth of recreational sailing, the
50 marina has been expanded after three years of construction and transformation. The marina is not spared by
51 siltation and has to spend 10% of its total budget to dredge around 200,000 m³ of cohesive sediment each year.
52 Thus, characterizing hydrodynamics and sediment flux is of key importance in this area where annual sediment
53 deposition can overpass 50 cm in some basins (Pers. Com. La Rochelle Marina).

54 This study aims to investigate the influence of floating structures on marina hydrodynamics by three-
55 dimensional numerical simulation. In the next two sections, we describe the area and methods used in the model
56 to perform realistic numerical simulations of water circulation at several temporal and spatial scales. Numerical
57 results are then compared against in situ observations before analyzing the influence of floating structures at the
58 marina scale. Their implementation is finally discussed before concluding.

59

60 **Description of the study site**

61 **La Rochelle Marina**

62 The study area is a 50 ha recreational port located along the French Atlantic Coast, in the central part of
63 the Bay of Biscay. It is located in the landward part of the Pertuis d'Antioche embayment, corresponding to a
64 drowned river valley segment (Chaumillon and Weber, 2006) and characterized by silty to sandy-silty bottoms.
65 This shallow water coastal area, protected from the Atlantic Ocean by the Ré and Oléron islands, is characterized
66 by a 44 m deep trench and many tidal flats (Fig. 1). Moreover, it is an urban marina with the city of La Rochelle
67 displaying a land area of 2843 km² and a population of 80,000 inhabitants.

68 Created in 1972, La Rochelle Marina has been the largest marina along the Atlantic coast, since its
69 expansion in 2014. This 900 m-long and 820 m-wide semi enclosed area is divided into 3 basins totaling 4500
70 moorings, distributed along 15 km of floating docks. The southwestern (SW) basin is larger, with 22 ha, whereas
71 the western (W) and the northeastern (NE) basins, contain 17 and 15 ha, respectively. The marina is accessible by
72 a 110 m wide main entrance, and the expansion basin has two openings: 150 m wide to the northeast and 64 m
73 wide to the southeast. To mitigate siltation, the marina requires recurring dredging of its basins, 8 months a year,
74 so that the whole marina is dredged every 3 years.

75 **Coastal area hydrodynamics**

76 The coastal area is considered a mixed, wave and tide-dominated estuary (Chaumillon and Weber, 2006).
77 The tidal schedule is semidiurnal and the tidal range varies from 2 m during neap tides to more than 6 m during
78 spring tides, where strong tidal currents can locally reach up to $2 \text{ m}\cdot\text{s}^{-1}$. Tides are dominated by M₂, and its
79 amplitude grows to more than 1.8 m in the inner part of the estuaries due to resonance and shoaling (Bertin et al.,
80 2012). Furthermore, the quarter-diurnal tidal constituents (M₄, MS₄ and MN₄) are strongly amplified shoreward,
81 because of resonance occurring on the Bay of Biscay shelf (Le Cann, 1990; Toubanc, 2015). The yearly average
82 significant wave height is approximately 1.5 m with periods between 8 s and 12 s, whereas wave height can be
83 larger than 8 m during winter storms in front of the Pertuis d'Antioche (Bertin et al., 2015). However, refraction,
84 diffraction and bottom friction in the inner part of the estuaries drastically decrease wave energy. Storm waves and
85 strong tidal currents are considered the main drivers of resuspension and contribute to a high level of turbidity at
86 the scale of the bay (Le Hir et al., 2010).

87

88 Numerical modeling

89 General description of the modeling system

90 In this study, we employed the TELEMAC 3D model (Hervouet, 2007), part of the open-source
91 hydrodynamic suite of TELEMAC system (Hervouet, 2000) adapted to free-surface flow modeling.

92 TELEMAC 3D is used and validated in a wide range of studies (Villaret et al., 2013; Bedri et al., 2011;
93 Kopmann and Markofsky, 2000; Cornett et al., 2010) by solving the following 3D Navier-Stokes equations:

$$94 \quad \text{div}(\vec{U}) = 0 \quad (1)$$

$$95 \quad \frac{\partial U}{\partial t} + \vec{U} \cdot \overrightarrow{\text{grad}}(U) = \frac{-1}{\rho_0} \frac{\partial p}{\partial x} + \text{div} \left(\nu_t \overrightarrow{\text{grad}}(U) \right) + f_x$$

$$96 \quad \frac{\partial V}{\partial t} + \vec{U} \cdot \overrightarrow{\text{grad}}(V) = \frac{-1}{\rho_0} \frac{\partial p}{\partial y} + \text{div} \left(\nu_t \overrightarrow{\text{grad}}(V) \right) + f_y \quad (2)$$

$$97 \quad \frac{\partial W}{\partial t} + \vec{U} \cdot \overrightarrow{\text{grad}}(W) = \frac{-1}{\rho_0} \frac{\partial p}{\partial z} + \text{div} \left(\nu_t \overrightarrow{\text{grad}}(W) \right) + f_z$$

98 where t is the time (s); x , y , and z the sigma-coordinates; U, V, W are the velocity components in the x , y , and z
99 directions ($m \cdot s^{-1}$); ρ_0 is the reference density ($kg \cdot m^{-3}$); p is the pressure term ($N \cdot m^{-2}$); ν_t is the turbulent
100 diffusion coefficients ($m^2 \cdot s^{-1}$) and f_x , f_y , and f_z are the source and sink terms ($m \cdot s^{-2}$).

101 Turbulence is modeled with k- ϵ model and the non-hydrostatic mode is used to perform simulations over
102 an unstructured grid (Fig. 2), from the regional (embayment) to local scale (marina), and at a large range of
103 temporal scales. Mesh is varying in function of the bathymetry and the area of interest, from 2 km offshore to
104 almost 5 m in the whole marina. Bottomstress is computed through the widely used Chézy parameterization (Rijn,
105 1984; Weitz et al., 1992; Deng et al., 2002; Nicolle and Karpytchev, 2007). The bottom frictional stress τ is then
106 represented by the quadratic relationship:

$$107 \quad \tau = \rho \frac{gU^2}{C^2} \quad (3)$$

108 where U is the vertically averaged velocity; ρ the water density ($kg \cdot m^{-3}$); g the gravity acceleration ($m \cdot s^{-2}$) and
109 C is the Chézy friction coefficient ($m^{0.5} \cdot s^{-1}$). We set spatially variable friction in the model by prescribing
110 different value of Chézy coefficient depending on the bottom nature. Following the methodology in Nicolle (2006)
111 concerning the Chézy parametrization in the Pertuis, we used a $100 m^{0.5} \cdot s^{-1}$ coefficient for mud, $80 m^{0.5} \cdot s^{-1}$ for
112 fine sand, $60 m^{0.5} \cdot s^{-1}$ for sand and $45 m^{0.5} \cdot s^{-1}$ for rocky bottoms.

113 The semi-implicit Galerkin finite element method is used to solve continuity and momentum equations. An
114 Eulerian–Lagrangian treatment of advective terms and a semi-implicit method insures numerical stability, even
115 with large time steps. The treatment of tidal flats ensured the conservation of mass and momentum. (Hervouet,

116 2015; Hervouet, 2011). Finally, wind effects are modeled as a two-dimensional condition at the water surface
117 through the equation:

$$118 \quad v_H \frac{\partial \overline{U}_H}{\partial \eta} = \frac{\rho_a}{\rho} a_w \overline{w} \|\overline{w}\| \quad (4)$$

119 Where \overline{w} is the wind velocity 10 m above the water surface ($m.s^{-1}$); \overline{U}_H is the horizontal velocity of the
120 water surface ($m.s^{-1}$); η is the elevation (m); ρ_a is the air density ($kg.m^{-3}$); and a_w the wind stress coefficient
121 defined by Flather, (1976).

122 **Model implementation**

123 The modeled area is 35 km wide and 100 km long and is discretized on a 41,000 node unstructured grid,
124 with resolution from 2 km offshore to nearly 5 m inside the marina. In this study, the coordinate system is converted
125 into a topography-following coordinate system via a sigma transformation. A sensitivity analysis has revealed that
126 the use of 8 vertical sigma levels was optimal/sufficient to reproduce three-dimensional circulation in the marina.
127 These sigma levels are treated with the Arbitrary Lagrangian-Eulerian method (Donea, 1982), and lead to 320,000
128 nodes. We use bathymetry from the French Navy (hereafter SHOM) and benefit from a twice per year single beam
129 survey in the marina. Then, the topography of intertidal areas are determined using LiDAR survey, acquired in
130 2010 (LITTO3D, French National Geographic Institute and SHOM).

131 Four kinds of boundary conditions are used in the model. Firstly, the coastline, that corresponds to a solid
132 boundary, where the friction governs the relation between velocity and its gradient. The bottom also plays the role
133 of a boundary wall where a spatially variable Chézy friction is imposed. Along, its open boundary, the model is
134 forced by 34 astronomical tidal constituents (O1, K1, P1, Q1, M2, S2, N2, K2, 2N2, MU2, NU2, L2, T2, M3, M4,
135 MN4, MS4, M6, M8, EPS2, MSF, MSQM, MM, SSA, SA, S4, MKS2, MF, LA2, J1, N4, MTM, R2, and S1),
136 obtained by linear interpolation from the global tide model FES2014 (Finite Element Solution - v.2014). Then,
137 the surface boundary of the model is forced with space and time variable sea-level atmospheric pressures and 10
138 m winds from the CFSR (The Climate Forecast System Reanalysis provided by the National Center for
139 Environmental Prediction), with spatial and temporal resolution of 0.5° and 1h. Atmospheric forcing is set over
140 the whole domain with hourly sea-level atmospheric pressure and 10 m wind speed and direction originating from
141 the Climate Forecast System Reanalysis (CFSR) provided by the National Center for Environmental Prediction
142 (NCEP). The hydrodynamic time step is set to 5 s after a sensitivity analysis. Observations (CREOCEAN,
143 unpublished data, 2004) showed that the marina is sheltered enough from ocean waves and is more sensitive to the
144 development of small wind-generated waves, in particular during storms where maximum wave height approach
145 15 cm. Thus, in the framework of this study, we did not simulate wave propagation.

Implementation of the floating structures in the model

Field trips involving the deployment of surface drifting buoys inside the marina have shown the complexity of water mass circulation. Steady currents and local eddies were visible at the channel entrance during the deployment; some buoys experienced stagnant conditions ($< 0.001 \text{ m.s}^{-1}$) while others were moved rapidly in the inner part of the marina by high intensity currents ($> 0.5 \text{ m.s}^{-1}$). Small-scale eddies and steady currents were also noticed near floating structures that, combined with the high density of docks and moorings in the marina, could have a significant impact on the velocity field in the inner part of the marina. Indeed, all the floating docks and moored boats represent more than a third of the total surface of this semi-enclosed area. Flows near floating obstacles were studied through numerical modeling and lab experiments (Tajali et al. 2008, Drobyshevski, 2004). However, they are poorly understood because of the complexity of three-dimensional unsteady currents and sensitivity to a large number of parameters (Martinuzzi and Tropea, 1993; Baker, 1980). To evaluate the effect of floating docks and moorings on the water mass circulation in the inner part of the marina, we conducted a modeling study with the presence of floating structures. Two methods are available with TELEMAC- 3D. The first is to locally increase the atmospheric pressure gradient to lower the free surface and apply surface friction according to the Nikuradse friction law. As it would have been computationally expensive to apply this method, we chose to implement a second method. This method consists of applying local head losses at each involved computational node. The head losses correspond to friction loss terms at the free surface that represent the flow resistance created by a rough surface in contact with the fluid. This method has been implemented in an implicit way as a source term in the three-dimensional momentum equations (2) via the following expressions:

$$\begin{aligned} f_x &= S1U.U \\ f_y &= S1V.V \\ f_w &= S1W.W \end{aligned} \tag{5}$$

With f_x , f_y , and f_z the source terms in three directions (m.s^{-2}) included in the 3D momentum equations; U , V , and W are the three velocity components (m.s^{-1}) and $S1U$, $S1V$, $S1W$ the intermediate terms (s^{-1}) defined by:

$$\begin{aligned} S1U &= C. \|U\| \\ S1V &= C. \|V\| \\ S1W &= C. \|W\| \end{aligned} \tag{6}$$

With C the coefficient corresponding to a friction coefficient (m^{-1}).

175 The nodes involved in the model correspond to the position of floating docks, whose draught varies between
176 0.5 m and 2 m with a mean value of 1.18 m for the whole marina. We independently integrated the two kinds of
177 structures in the model. A third of the marina surface nodes were affected by this implementation. In term of CPU
178 time, simulations with floating structures requires about one-quarter higher CPU time than basic simulations.
179 Using forty cores of a supercomputer, it approximately leads to a total of 20 hours to simulate 15 days with 8 sigma
180 layers.

181 This method is relatively sensitive to mesh resolution, which has been considered in our numerical
182 simulations. A sensitivity analysis was performed to calibrate C in agreement with field observations. The
183 calibration of C was performed with one measurement point (visible in validation section). The best C coefficient
184 was found to be $0.6 m^{-1}$ for mooring boats and $0.5 m^{-1}$ for floating docks. During the calibration process, a large
185 number of C coefficient was tested, ranging from 0.1 to $2 m^{-1}$ and the modeled results were found consistent with
186 the observations for a C coefficient ranging from 0.3 to $0.8 m^{-1}$.

187 **Validation**

188 **Water levels**

189 The model was calibrated and validated using water level measurements taken offshore and inside the
190 marina (the white stars with red borders in Fig. 1). La Pallice data (radar) were collected through the REFMAR
191 portal (data.shom.fr/), and water levels in the marina (pressure sensors) were acquired in March 2017. The
192 comparison between numerical results and 10-minute continuous time series measurements (Fig. 3) shows a Root
193 Mean Squared Error (RMSE) of 0.18 m for La Pallice with 0.17 m average for the four stations in La Rochelle
194 Marina (Table 1). Globally, water levels are very well reproduced by the model at the five stations with errors
195 about 3-4%, once normalized by the mean local tidal range. Offshore, at the other stations (Fig. 1), water levels
196 are also well reproduced with the same level of error (Table 1). It is also important to note that there are few
197 differences in the water level signal between simulations with and without floating structures.

198

199 **Current in the channel entrance**

200 Three ADCP current-meters were deployed in 2014 by the CREOCEAN engineering company, after the
201 marina expansion (black stars 1, 2, 3 in Fig. 1). In this section, we display vertical profiles of current at the marina
202 entrance (black star 1 in Fig. 1) obtained during spring tides where the mean tidal range was approximately 6
203 meters. Observations revealed a strong distortion of the tide at the entrance, with a strong tidal flood that is not
204 compensated, in terms of intensity, during ebb; during spring tides, current can overpass $1.5 m.s^{-1}$ at the

205 beginning of flood tide and reach $0.8 \text{ m} \cdot \text{s}^{-1}$ at the end of ebb tide. Fig. 4 displays the comparison between
206 numerical results obtained with floating structures and the observations. Surface velocity was observed 0.5 m
207 below the free surface and bottom velocity was observed 1.5 m above the bottom. The model faithfully reproduces
208 this behavior, with a very good reproduction of the peak flow of the ebb and flood tides. Moreover, speeds are
209 relatively in phase, from the bottom to the surface and the main directions (north at flood and south at ebb) are
210 well reproduced. Table 2 summarizes the differences between numerical results and in situ observations of current
211 both in terms of intensity and direction. RMSE is approximately $0.07 \text{ m} \cdot \text{s}^{-1}$ and 51.3° for intensity and direction,
212 respectively. The model underestimates velocity by less than 2%, mainly due to underestimating peak flows. For
213 a simulation without floating structures, the current behavior is similar, with a slight intensity decrease during peak
214 flows (approximately $0.05 \text{ m} \cdot \text{s}^{-1}$).

215

216 **Currents in the vicinity of the marina**

217 To better understand the dynamics of the marina, an up-looking ADCP current-profiler (Aquadopp
218 Profiler, 2 Mhz, 20 cm cells) was deployed just below floating docks (black star 4 in Fig. 1). Data acquisition
219 displayed vertical accuracy of approximately $0.008 \text{ m} \cdot \text{s}^{-1}$ and horizontal accuracy of approximately 0.003
220 $\text{m} \cdot \text{s}^{-1}$. The aim of this instrumentation was not only to understand how currents are modified by the presence
221 of floating docks but also to calibrate and compare our modeling system in the inner parts of the marina. The 5-
222 day measurement occurred from April to May 2018, with a relatively important tidal range (4 to 5 meters) and
223 calm weather (mean wind speed approximately $5 \text{ m} \cdot \text{s}^{-1}$). Fig. 5 shows the comparison between simulated and
224 measured velocity for one day. Measured velocity displays the maximum current during the flood 2 hours after
225 low tide but, contrary to the channel entrance, the water column is stratified. Indeed, the velocity is stronger at
226 the bottom (Fig. 5A). Then, floating structures appear to have a role in the attenuation of surface velocity. A
227 preliminary calibration of the friction loss coefficient has been carried out to fit the model results to
228 measurements in the inner part of the marina. The corresponding results for the period of acquisition are shown
229 in Fig. 5B, and the simulations without floating structures are shown at the bottom (Fig. 5C). The simulation
230 without floating structures overestimates the velocity by a factor of two during peak flow. No stratification is
231 found in the water column. In terms of current intensity, current seems quasi-homogeneous as at the channel
232 entrance (Fig. 4). The simulation with floating structures, better reproduces the measured velocity order of
233 magnitude of approximately $0.07 \text{ m} \cdot \text{s}^{-1}$ during peak flow. Moreover, the stratification is well represented and
234 fits the measurements. There is still some bias compared to reality: the attenuation along the vertical axis is not

235 strong enough and the ebb tide is slightly overestimated. This behavior is displayed in Fig. 6 where a comparison
236 is provided in term of intensity and directions. Directions are more dispersed and less channeled than in the
237 channel entrance (Fig 4) and their reproduction is slightly worse with a $75,8^\circ$ RMSE and $-12,5^\circ$ bias. However,
238 the main directions are preserved with the model with FS compared to the model without FS that generates more
239 channelized directions of different direction. Comparison of surface velocity (Fig. 6), observed 0.5 m below the
240 free surface, confirms the overestimation by the simulation without floating structures. Between measurements
241 and numerical results, a $0.064 m \cdot s^{-1}$ RMSE is reached, with maximum error of approximately $0.10 m \cdot s^{-1}$. With
242 floating structures in the simulation, the peak flow occurred in phase with measurements, and accurately fit the
243 magnitude of intensity. The RMSE is much better, with $0.012 m \cdot s^{-1}$ accuracy for a maximum error
244 approximately $0.025 m \cdot s^{-1}$ and an average overestimation of 0.5%.

245

246 **Results**

247 **Tidal circulation in the marina**

248 Hydrodynamic simulations were performed under tidal and meteorological forcings. Even if wind forcing can
249 influence velocity fields, considering the relatively shallow depths of the water column, numerical modeling
250 suggests a major impact for tide on the currents. Then, contrary to the Bilbao (Grifoll et al., 2009) and Genoa ports
251 (Cutroneo et al., 2017), density-driven circulation is considered nonexistent in La Rochelle marina. Indeed, there
252 is no freshwater influence except during occasional heavy rainfall. Therefore, in this section, the modeled results
253 are analyzed assuming that the tide is the main factor controlling the water circulation pattern.

254 The main circulation patterns are shown in Fig. 7. The depth-averaged velocity displayed was computed for
255 a spring tide (tidal range = 6 m), with and without the implementation of floating structures in the model. The
256 maximum velocity in the marina is located in the channel entrance at the end of the ebb and beginning of the flood,
257 when the section is the lowest. The behavior of water bodies during flood and ebb is very different. A strong flood
258 enters the marina by the main entrance with maximum amplitude up to $1.7 m \cdot s^{-1}$, 1 hour after low tide, whereas
259 the ebb is two times lower in intensity and mainly focused on the channel entrance. At the end of ebb tide the
260 current is rapidly reversed by the flood at the channel entrance. The opposition between these two flows leads to
261 complex current in terms of direction and intensity. Current presents a large range of intensity substantially
262 influenced by basin geometry. For instance, a W basin displays stagnant water with velocity lower than 0.01
263 $m \cdot s^{-1}$, reaching only $0.05 m \cdot s^{-1}$ at peak flow. During neap tide, where the tidal range is approximately 2 m, the

264 velocity decreases by a factor of two, but the same trend remains in the marina. The main changes occur during
265 ebb with weak eddy reduction and lower water flux compared with spring tide.

266 At the entrance sections, there is an asymmetry in term of flood-ebb duration, which is inverse function of the
267 tidal range. At the main entrance (section 1), during spring tides there is a 5 h 30 min – 6h 40 min ratio against a
268 4 h 30 min – 7 h 20 min ratio during neap tides but fluxes at the entrances are globally enhanced during flood. The
269 tidal asymmetry of the offshore area explains this asymmetry of flux between flood and ebb tide, as discussed
270 earlier (Guo et al., 2018). The asymmetry can also result from signal distortion generated by the system geometry
271 (quays, entrances sections) and bathymetry (Nece and richey 1972; Sztano and De Boer, 1995).

272

273 **Impact of floating structures on marina tidal circulation**

274 The main difference between the simulation with and without the floating structures concerns the flood. With
275 FS, there is a faster velocity decrease and faster divide of the entering flood into two directions. Furthermore, the
276 addition of floating structures reduces the development of eddies at the scale of each sub-basin (Fig. 7A and 7B).
277 Once the stream enters the W and SE basins, we observe a strong decrease in eddy intensity in surface layers and
278 a very strong reduction in the size and intensity of the eddies. During the ebb, water circulation is slightly
279 noticeable in the inner part of the marina. Consequently, the impact of floating structures in the model is weak.
280 Indeed, the main currents are located along the channel entrance, which appears to be slightly impacted by the
281 presence of floating structures. During flood and ebb tide the maximum velocity along the channel entrance is
282 slightly accentuated by floating structures (Table 3). The southern part of the W and SE basins are the most
283 impacted by the attenuation of velocity, displaying large stagnant water areas (Fig. 7G and 7H) where intensity is
284 lower than $0.01 \text{ m} \cdot \text{s}^{-1}$ except during the flood where intensity can reach $0.05 \text{ m} \cdot \text{s}^{-1}$.

285 Quantitatively, Table 3 reveals the impact of the implementation of floating structures on the velocity field of
286 the marina. The effect is more significant during spring tides when currents are stronger. From neap to spring tides,
287 in the W basin, velocity intensity was reduced from 8% to 28%, respectively. In the SW basin, the velocity was
288 reduced from 3% to 15%, respectively, and in the NE basin, the main reductions were 10% and 65%, respectively.
289 However, the velocity decrease in the inner parts of the marina is compensated by velocity acceleration in other
290 locations. The relatively higher velocity during ebb supports this assertion with the presence of floating bodies
291 (Table 3).

292 The effect of floating structures increases towards the inner parts of basins. Their presence attenuates currents
293 at the surface that consequently reduce the currentology of the inner parts of the marina.

Residual flux at the marina entrances under the action of tides and wind

The wind regime in the area, and more globally in the whole Bay of Biscay, experiences a significant interannual variability (Dodet et al. (2010)), which is partly controlled by the North Atlantic Oscillation. The weakest winds, lower than $4 \text{ m} \cdot \text{s}^{-1}$, occur 58% of the time, moderate winds, from 4 to $8 \text{ m} \cdot \text{s}^{-1}$, occur 29% of the time and the strongest, from 8 to $16 \text{ m} \cdot \text{s}^{-1}$, occur 12% of the time. Summer presents weak low-pressure system activity resulting in weak winds mostly originating northeasterly while the littoral is mainly dominated by thermic breezes from the north-west. During autumn, low-pressure systems cross the Atlantic Ocean, creating more energetic winds from south-west to west. These low-pressure systems are most active during winter, and they can potentially cross the French Atlantic coast where strong winds are often observed. These systems result in the predominance of four winds over the area of study: northwestern (22% occurrence), western (21% occurrence), northeastern (19% occurrence) and southern (14% occurrence) winds.

To understand the role of the wind in the area, twelve specific cases were studied, corresponding to six atmospheric conditions (one without wind, four with an average $7.5 \text{ m} \cdot \text{s}^{-1}$ wind from several directions, one with a strong $15 \text{ m} \cdot \text{s}^{-1}$ wind from the west) linked with 2 tidal conditions (spring and neap tides). Residual flux (RF) was computed over five tidal cycles, at three different sections for every case. The first case corresponds to a situation with only tides; the four following are simulations of combined tide and wind forcing related to the four dominant area winds. These five cases were simulated for a spring tide with 6-meter tidal range and a neap tide with 2-meter tidal range. Three sections were defined in this study to compare residual flux (Fig. 8).

This study shows that the total RF in the marina is a general inflow mainly governed by section 3. For neap and spring tides, the configuration is the same with an offshore RF at section 1 and 2 and an onshore RF at section 3. The only difference is that RF are significantly higher during spring tides. The presence of a west wind enhances the westward residual circulation established from section 3 to section 1. This residual dynamic is also conserved, but with less intensity, when the wind is northwest. With a northeast wind, this residual circulation is completely reversed and oriented from section 1 to section 3. RF for simulations with a southern wind is not presented in Fig. 8 because it is relatively unchanged compared with no-wind simulations. Depending on its direction, the wind has an anisotropic effect, which can be significant in particular during neap tides. Finally, it is important to notice that the absence of floating structures in the model does not noticeably affect the RF at the sections.

324 **Assessment of the main drivers of circulation**

325 To more accurately investigate the influence of the water circulation-driving mechanisms, velocity depth
326 average was computed with numerical modeling and analyzed for the 12 specific cases. The mean differences
327 between states without and with wind stress, regardless of direction, range from $0.02 \text{ m} \cdot \text{s}^{-1}$ to $0.01 \text{ m} \cdot \text{s}^{-1}$ with
328 maximum difference of approximately $0.70 \text{ m} \cdot \text{s}^{-1}$ during the maximum flood/ebb tide. Table 4 reveals the mean
329 velocity averaged over 5 tidal cycles for several wind directions. Large differences appear according to wind
330 directions but, globally, wind decelerates water mass dynamics during spring tides and accelerates them during
331 neap tides. For spring tides, only a $7.5 \text{ m} \cdot \text{s}^{-1}$ south wind is able to increase the water circulation whereas other
332 winds decrease circulation (up to 25% for an NE wind). During neap tides, the west, northwest and south winds
333 increase velocity up to 34%, whereas the northeast wind only increases it by 14%. The behavior of water masses
334 is consistent, first with the direction of tidal propagation in the bay for a northeast wind and second with the
335 direction of channel entrance for a south wind. More generally, average winds have a significant influence on
336 velocity mainly during neap tides. Strong events as $15 \text{ m} \cdot \text{s}^{-1}$ west winds that occur frequently during winter in
337 the area, can overpass the tidal forcing by increasing the neap tides velocity by more than 50%. Finally, the results
338 show that the significant influence of the wind follow the same trend with and without floating structures (Table
339 4). However, while their effect is similar during spring tides (a decrease of the mean velocity), the wind and the
340 floating structures display an antagonistic effect during neap tides by increasing and decreasing the velocity,
341 respectively.

342 **Discussion**

343 **Relevance of considering floating structures in the model**

344 Structures such as floating docks and breakwaters are often encountered in the modeling domain, but their
345 effect is often neglected. This effect can be very complex to incorporate in some applications. Tsay and Liu (1983)
346 and Li et al. (2005) proposed an approach to approximate the effect of floating structures in a 2D elliptic harbor
347 wave model. However, a simplified approach has permitted us to simulate their effect on hydrodynamics. Indeed,
348 comparison with observations has shown the necessity to implement floating structures in order to better fit the
349 reality. Even if floating structures have not a real effect on residual flux, a strong influence of floating structures
350 has been identified. The main impact is the drastic reduction of microscale eddy structures in the inner part of the
351 marina (Fig. 7B). The velocity intensity has decreased by more than 30% in the whole marina whereas the NE
352 basin displays a maximum attenuation of 65% (Table 3). This reduction is compensated by a slight velocity
353 increase in the channel entrance during peak flood and ebb flows. These significant differences between the model

354 with and without floating structures raised questions about the resuspension and siltation of the marina. Therefore,
355 it appears relevant that a highly populated port should consider the effect of floating docks and boat moorings in
356 any hydro sedimentary modeling study.

357 Further research needs to be carried out to characterize the influence of floating structures on wind stress.
358 Indeed, the effect of wind is decreased by floating structures and that could have a significant impact on water
359 agitation and hydrodynamics in the marina. The results show that the influence of wind, in terms of velocity
360 intensity, is weaker with the presence of floating structures. The floating structures naturally decrease the wind
361 effect by “protecting” the surface. As both the influence of wind and implementation of floating structures in the
362 model mainly concerns the surface layers, our methodology also considers the wind decrease effect on the marina.

363 It is also important to consider some limitations of this study. First, we do not explicitly represent floating
364 bodies as obstacles in the flow field. We considered floating structures only in the momentum equation while in
365 reality they also affect the depth-integrated continuity equation. This simplification could result in an
366 underprediction of current velocity between floating structures, as there is no contraction of the hydraulic section.
367 Then, we do not consider the motion and dynamic forces of the floating structures. In our methodology, we do not
368 model these effects, but we are trying to estimate the global effect of floating bodies at the scale of the entire
369 marina. It is also important to note that our method is sensitive to the number of vertical sigma layers used in the
370 study as well as the number of layers involved in the representation of floating structures.

371

372 **Impact of floating structures on eddy generation**

373 Even with the implementation of floating structures, transient small-scale eddies are generated in the inner
374 part of the marina from the flood beginning until the ebb (Fig. 7A, 7B, 7C and 7D). This behavior is the result of
375 tidally driven flow separation at the channel entrance that ensures eddy development behind the quays. It is a well-
376 known phenomenon that has been easily reproduced by barotropic numerical models (Pingree and Maddock, 1977;
377 Imasato, 1983; Signell and Geyer, 1991). These are considered topographic eddies (Babu et al., 2005; Vethamony
378 et al., 2005). The geometry of the marina leads to a considerable difference in terms of eddy structure intensity
379 between flood and ebb tide. Whereas ebb tide is characterized by the absence of eddies, the flood time displays
380 eddies of basin size. Depending on tidal and wind forcing, the number and size varies from between 2 and 3 eddies
381 in the W basin, to 3 to 5 in the SW basin and 1 to 3 in the NE basin (Fig. 7). The number and size are dependent
382 on hydrodynamic conditions, the geometry of the marina and its bathymetry (presenting strong lateral gradients
383 due to recurring dredging). Nevertheless, the presence of floating structures substantially reduces their action and

384 intensity by concentrating flow at the channel access. Although the natural generation of eddies during the flood
385 is conserved, their presence leads to a channeling of the flow that also has an impact on residual circulation.

386 **The role of residual circulation in particle residence time**

387 According to Babu et al. (2005) tide-topography interaction is the main mechanism generating residual
388 eddies because topographic variations in the eddy region slow tidal wave propagation, inducing a phase shift. In
389 La Rochelle Marina, residual flow computed from the averaging of depth-averaged currents over 5 tidal cycles
390 presents microscale eddies. In terms of size and location, these eddies correspond to the topographic eddies created
391 by tide-topography interaction during the flood discussed earlier. Their intensity is weaker, and it can reach a
392 maximum of $0.2 \text{ m} \cdot \text{s}^{-1}$ intensity in the NE basin, during spring tides.

393 Our results show that the presence of both average $7.5 \text{ m} \cdot \text{s}^{-1}$ wind and floating structures is sufficient to
394 significantly affect the shape and intensity of residual eddies. Whereas wind stretches the tide-induced eddies in
395 its direction of propagation, the floating structures focus the residual flow on the channel entrances. The wind and
396 floating structures alter the residual circulation of the marina differently; although the former modifies the RFs
397 substantially at the entrance section, the latter reorganizes residual flow without really modifying RFs.

398 Vethamony et al. (2005) suggested the contribution of residual eddies to the net transport of material from
399 the system and their potential role in the transport of pollutants. Although Wolanski and King (1990) presented
400 enhancement by eddies by flushing process, long term-transport is altered by the presence of residual eddies,
401 reducing the flushing rate (Babu et al., 2005). Thus, questions are raised about particle residence time and more
402 generally about water quality. Floating structures could influence significantly the residence time of particles or
403 discharged material in the marina. To address this question, further research is conducted to characterize water
404 mass exchanges under the influence of wind and tide forcings, with the presence of floating structures.

405 **Conclusion**

406 This paper presents the influence of floating structures on the hydrodynamics of a highly populated marina.
407 Assessment of the main driving mechanisms, tide and wind forcings, has been conducted and an original
408 implementation of floating structures was conducted and discussed. In situ velocity measurements have shown
409 model overestimation without floating structures in the inner parts of the marina. Conversely, the implementation
410 of floating bodies has permitted one to fit observations and highlight their strong influence on the attenuation of
411 current. This reduction in intensity is mainly compensated by a slight increase in the access channels during peak
412 flow. Furthermore, the residual circulation is also impacted by their presence; the residual eddies naturally formed

413 in the marina by tide-topography interaction are strongly attenuated. As tidally induced eddies play an important
414 role in the dispersion of matter (Yanagi, 1974), they could decrease this dispersion as well as the resuspension.
415 Thus, questions are raised about water quality, siltation and more extensively, dredging maintenance strategy.

416 Even if the area is under the influence of a macrotidal regime, the role of wind is also undeniable; although
417 significant during spring tides, its influence can be dominant during neap tides, approaching 50% in terms of mean
418 velocity. Wind also affects the residual circulation, by modifying the size and form of eddies and by reversing the
419 RFs. To assess the relative importance of the different processes a study is being conducted. Its objective is to
420 characterize particle residence time under tidal and wind forcing with the presence of floating structures.

421

422 **Data Availability Statement**

423 Some observed and simulated data generated and used during the study are available from the corresponding
424 author by request (simulated and observed water level obtained in 2017 and currents obtained in 2018).

425 The code used during this study is available in a repository online in accordance with funder data retention
426 policies (<http://www.opentelemac.org/>).

427 Some data used during the study are proprietary or confidential in nature and may only be provided with
428 restrictions (CREOCEAN is the owner of the observed currents data obtained in 2014. To acquire these data and
429 to know the restrictions associated, you should ask directly with CREOCEAN).

430 Some data used during the study were provided by a third party (Atmospheric data provided by NCEP, offshore
431 water levels provided by SHOM, bathymetric data provided by SHOM without restrictions).

432

433 **Acknowledgements**

434 This work was funded by Région Nouvelle-Aquitaine, La Rochelle Marina and the CPER (“Contrat Plan Etat
435 Région”) DYPOMAR. The developing team of TELEMAC is warmly acknowledged for making its code available
436 and providing useful discussion. Water level data originate from the REFMAR network (SHOM) and the
437 atmospheric forcing was provided by the National Center for Environmental Prediction (NCEP). We also thank
438 CNRS and the Université de la Rochelle for their support and Xavier Bertin for the review and helpful advice.

 577 **Fig. 5.** Comparison of velocity intensity ($m \cdot s^{-1}$) computed with floating structures (B), without floating structures
 578 (C) and acquired with ADCP (A) in the inner part of the western marina basin for one day in May 2018 (mean
 579 tidal range = 4 meters). FS corresponds to floating structures.

581
 582 **Fig. 6.** Comparison of velocity computed with floating structures (gray line), without floating structures (black
 583 line) and acquired with ADCP (red) inside the marina for three days in May 2018 (mean tidal range = 4 meters).
 584 FS corresponds to floating structures.

 586 \rightarrow
Fig. 7. Depth-averaged velocity field ($\text{m} \cdot \text{s}^{-1}$) for simulations with (right) and without (left) floating structures. A
 587 and B correspond to flood. C and D correspond to high tide. E and F correspond to ebb. G and H correspond to
 588 low tide.

589
 590 **Fig. 8.** Residual fluxes ($m^3 \cdot s^{-1}$) at the entrances defined in the top figure for several conditions of wind and tides.
 591 A ,B, C, D correspond to neap tide conditions and E, F, G, H correspond to spring tide conditions. A-E represent
 592 the situation without wind and B-F, C- G, and D-H, correspond to simulations with $7.5 m \cdot s^{-1}$ west, northwest, and
 593 northeast winds.

616 **Tables**

617

618 **Table 1.** Metrics between numerical results and measurements

	RMSE (m)	Maximum Errors (m)	Bias (m)
La Rochelle Marina	0.17	0.25	0.08
La Pallice	0.18	0.30	0.13
La Cotinière	0.19	0.31	0.17
Bourcefranc-le-Chapus	0.19	0.31	0.11

619 Note: RMSE = Root Mean-Squared Error.

620 Measurements were taken at the several tide gauges corresponding to white stars bordered in red in Fig. 1. Metrics
621 for La Rochelle Marina are averaged for comparison between numerical results and data from the four tide gauges
622 deployed in the marina.

623

624 **Table 2.** Metrics between depth-averaged numerical results and ADCP measurements of velocity

	Intensity ($m \cdot s^{-1}$)			Direction (degrees)	
	RMSE	Maximum Errors	Bias	RMSE	Bias
ADCP 1	0.072	0.16	0.032	51.3	20.1
ADCP 2	0.065	0.12	0.028	46.1	11.2
ADCP 3	0.069	0.17	0.034	62.3	24.8
ADCP 4	0.064	0.10	0.091	129.7	-68.4
(without FS)					
ADCP 4	0.012	0.02	0.005	75.8	-12.5
(with FS)					

625 Note: FS = floating structures

626 ADCP measurements were acquired during three spring tide days in October 2014 (ADCP 1, 2 and 3), and in May
627 2018 (ADCP 4).

628

629 **Table 3.** Depth averaged velocity computed in the marina for spring and neap tides.

	Spring tides ($m \cdot s^{-1}$)	Neap tides ($m \cdot s^{-1}$)
WB	0.50 (0.76) – 0.81 (0.80) – 1.17 (1.50)	0.12 (0.14) – 0.15 (0.11) – 0.27 (0.34)
SEB	0.61 (0.74) – 0.94 (0.81) – 1.45 (1.59)	0.13 (0.14) – 0.23 (0.23) – 0.37 (0.43)
NEB	0.25 (0.73) – 0.39 (1.01) – 0.73 (1.56)	0.07 (0.08) – 0.09 (0.10) – 0.38 (0.45)
CE	0.90 (0.89) – 1.19 (1.16) – 1.68 (1.68)	0.23 (0.23) – 0.19 (0.17) – 0.59 (0.58)
Total Marina	0.56 (0.75) – 1.19 (1.16) – 1.68 (1.68)	0.14 (0.18) – 0.23 (0.23) – 0.59 (0.58)

630 Note: WB = western basin; SEB = southeastern basin; NEB = northeastern basin; CE = channel entrance.

631 Each entry corresponds to mean velocity, maximum velocity during ebb, and maximum velocity during flood,
632 with (and without) floating structures in several parts of the marina.

633

634

635 **Table 4.** Depth averaged velocity for several configurations of tides and wind

	Spring tides ($m. s^{-1}$)	Neap tides ($m. s^{-1}$)
No wind	0.56 (0.75)	0.14 (0.18)
WW(15 $m. s^{-1}$)	0.50 (0.70)	0.29 (0.42)
WW (7.5 $m. s^{-1}$)	0.49 (0.65)	0.18 (0.22)
NWW (7.5 $m. s^{-1}$)	0.44 (0.60)	0.20 (0.22)
NEW (7.5 $m. s^{-1}$)	0.42 (0.56)	0.16 (0.19)
SW(7.5 $m. s^{-1}$)	0.57 (0.64)	0.21 (0.25)

636 Note: WW = west wind; NW = north-west wind; NEW = north-east wind; SW = south wind.

637 Each entry corresponds to the total mean marina velocity computed over 5 tidal cycles for 6 specific cases with

638 (and without) floating structures: without wind, with strong 15 $m. s^{-1}$ WW (typical storm wind during winter),

639 and four with a 7.5 $m. s^{-1}$ wind.
